drawing on the construct motivation, is discussed and three hypotheses generated: (1) that Vrccm's model does predict performance in a non-industrial setting; (2) that it predicts self-rerceived performance letter than measures externally derived; and (3) that a measure of self-rated expectancy increves the predictive power of the model. All three hypotheses were confirmed on a sample of 33 members of a university wrestling team. Interviews and questionnaire were used to collect relevant data from team members and coaches. Sample items from the questionnaire are included. (TI)

Vroom's model purposes to both explain and predict an individual's level of work productivity by drawing on the construct, motivation. Beginning with the premise that most work behavior is voluntary, and thus motivated, the theory is aimed at identifying the underlying components of this motivational base. The model delineates the manner in which these underlying components combine, resulting in a ubiquitous force upon the individual. The behavioral manifestation of this force is revealed in the amount of effort expended to achieve some desired performance level.

Move specifically, an individual's motivation to perform at some given level can be explained, Vroom contends, by defining those outcomes or consequences which the individual associates with that performance level. The degree to which any one of these outcomes actually contributes to the motivational base is a multiplicative function of two factors: the valence or anticipated satisfaction or dissatisfaction to be devived from that outcome, and the perceived probability that the outcome will or will not be realized upon attainment of a given level of performance. Vroom refers to this latter notion as the instrumentality of performance level "X" for the attainment of outcome "Y". Thus, for example, in order for supervisor approval to serve as a motivator or inducement for high performance, the worker must body desire the supervisor's praise (positive valence), and also feel that increased performance will increase the probability of receiving this approval (positive instrumentality). In addition to these notions about the motivating function of associated outcomes, the model also states that the individual must real that he has control over his performance level. This is denoted in the model as expectancy. In the context of the previous example, even though the subject desires a supervisor's approval and sees it as contingent upon performing at a certain level, this outcome will not motivate him unless he feels he is capable or has the potential to achieve the necessary performance criterion.

Previous attempts to determine the validity of Vroom's model have been conducted either in actual industrial settings (Galbraith & Cummings, '67; Hackman & Porter, '68) or in "experimental simulations" of industrial environments (Graen, '69). This trend is not surprising since when Vroom introduced the model in 1964, the primary emphasis was placed on its application in industrial-organizational contexts. However, it is our contention that there are no intrinsic characteristics of the model which should restrict its utility solely to industrial environments. On the contrary, the model should be an equally powerful tool in virtually any performance setting.

Consequently, one of the purposes of this study was to extend the validity of the model through an assessment of its predictive power in a non-industrial miliou. A second goal was to test a proposed modification of the theory. Vroom's model has been evaluated in terms of its ability to account for variations in performance. Without exception, the measure of performance predicted was derived by some external, often called objective means, for example, unit-output records. However, the model vroom espouses is distinctly cognitive. Emphasis in all the independent measures is on the perceptions or cognitions of the individual, that is, self-rated valence, self-rated instrumentality, and self-rated expectancy. Hence it is with some trepidation that this author learns that in the quantification of the dependent variable productivity, the perceptions of the focal individual are completely ignored.

Is it not reasonable to view cognitively derived, self-perceived performance as an intervening variable between the motivational base and "objective" performance. Vroom argues that a worker adjusts his performance to a force impinging upon him to attain a certain level of output. But performance for the individual is defined by his perceptual and cognitive processes. It therefore seems defensible that it is this cognitive index of performance that the worker adjusts to this force, and as a result it is this measure of performance that is in fact predicted

by the theory. What success the model has enjoyed as a predictor of various other indicies of performance may reasonably be explained by the sizable correlation extant between self and other ratings of this variable (Parker, '59; Koppel, '70). The present study was designed to generate some data relevant to this question.

A final purpose was to examine the contribution made by the expectincy notion. Galbraith and Cummings ('67) conducted an investigation which provides heretofore, the most complete test of Vroom's model. Unfortunately, they failed to measure expectancy. It was their contention that the research setting in which the study was conducted was such that their subjects had complete freedom to regulate their output level. Consequently, they simply assumed expectancy was equal to unity. While objectively this assumption may be justified, the model calls for perceived, not objective expectancy. Their subjects, for a wide variety of reasons, may not have felt that their rate of output was entirely under their own control. Consequently, although they did find some evidence for the model, its potential efficacy may well have been attenuated.

In the present study, although we too fels expectancy might equal unity, a measure of the subject's perception was included.

In sum then, the present endeavor addresses itself to three issues. First, would Vroom's model predict performance in a non-industrial setting? Second, does the model in fact predict self-perceived performance better than measure: externally derived? And finally, will a measure of self-rated expectancy improve the predictive power of the model?

Procedure

Thirty-three members of the Iova State University Wrestling Ream completed questionnaires designed to yield the information required by the model. The five performance related outcomes about which data were collected were derived through interviews with former team members and the three team coaches. These comes are: 1) support from coaches, 2) respect of teamates, 3) winning matches,

4) making the starting team, and 5) becoming too timed to study after practice. Presumably this last outcome was negatively valent, although admittedly for some of these athletes, the obverse is true. The dependent variable was defined as the amount of effort put forth in daily practice sessions by a wrestler. Ratings on this variable, as well as on ability were collected for every wrestler from each of the three team coaches. In addition, each wrestler indicated in the questionnaire how he perceived his own relative level of effort. Sumple items from the questionnaire are shown in the handout.

After transformation of all scores to deviation form, a test of the applicability of Vroom's model in this setting was made by regressing coach-rated effort on the full model. This is labeled Eq 1 in the handout.

A second regression, Eq 2, was run on self-rated effort and a comparison of the multiple r² from this regression was made with the r² obtained in Eq 1. This provided a test of the hypothesis that the model predicts self- not coach-rated effort.

Finally expectancy was deleted from the model to test for the hypothesized loss of predictive power when this variable is assumed to equal unity.

Results and Discussion

Since it is our position that a modification in the definition of the dependent variable is needed, let us examine this point first. This will enable us to discuss the remaining hypotheses in light of the model which proves to be more appropriate.

Vroom's full model was regressed on coach-rated and then self-rated effort. Subsequently, a test devised by Pitman was employed to test for a significant difference in variance explained by the two models. The results are displayed in Table 1. As can be seen, the residual variance from the regression on coach-rated effort is significantly greater than that remaining after the regression on self-rated effort (t=3.04;df=26;p<.01). Thus the hypothesis that Vroom's

(In the one hand, we can view the model as a predictor of perceived performance, as has been argued. If we do, then by definition self-matings are more appropriate. However, if we choose to regard performance as a behavioral rather than a cognitive construct as above, what relevance has this finding?

If we take a behavioristic approach to performance, we assume that there is rose "true" livel of performance that describes each wrestler. Our problem then becomes one of finding the better estimate of this have level. Assuming that self-ratings do provide a better estimate of true performance than do coach-ratings, several possible explanations for this exist.

One conceivable explanation is that through definitional confusion over the construct to be rated, that is, effort, the coaches were actually rating a slightly different construct than were the wrestlers. Since the two ratings had only 50% of their variance in common, this explanation seems viable. However, when we correct for the attenuation due to the unreliability of each measure, they correlate perfectly. Hence, the explanation that we have estimates of two different constructs seems unlikely.

the predictability of coach-rated versus self-rated effort. Where is some evidence that self-ratings on a number of dimensions correlate more highly with one another than self and other ratings on these dimensions (ef. Reppel & Sechiest, '70). Consequently, we might expect a greater correlation between self-rated effort and the self-rated variables of expectancy, valence, and instrumentality than obtained with the heterogeneous combination of coach-rated effort and self-rated independent variables. In short, in the former case we need only contend with trait variance, whereas in the latter, both method variance (different raters) and trait variance are potential sources for error in our measures. In this study it is not possible to determine the degree to which this differential

method variance has forced the obtained results.

A final explanation for the superiority of self-rated effort as a critemicn is that this estimate of true effort has greater criterion relavance. It is this account that we endorse. Since the individual wrestler has a far larger sample of his "effort" behavior than does a coach who must observe an entire team, it is likely that his estimate is a better approximation to true effort. Furthermore, it is difficult for a coach to separate effort from ability in his ratings. For example, two wrestlers may appear to be working equally hard, but if one is shorter-winded than the other, he must exert greater effort. Certainly a wrestler rating himself is in a better position to take these considerations into account.

Presuming for the moment that in the last five minutes I have succeeded in establishing self-ratings as the more appropriate criterion in the model, let us now turn to the remaining hypothesis.

The second major question addressed in this endeavor concerned the applicability of Vroom's model to a non-industrial milieu. When the self-rated effort was regressed on the full model, a correlation of .65 resulted. As is shown in Table 1, this is significant beyond the .025 level. The hypothesis that the model is applicable in a non-industrial setting was thereby confirmed.

Finally, the hypothesis that the actual measurement of expectancy would improve the predictive power of the model also received confirmation. Significanlty more variance was explained when expectancy was included in the regression equation than when it was omitted, $F_{6,20}^{-3}3.23$, p<.025 (compare Table 1 with Table 2). This finding underscores the importance of actually measuring all constructs in a cognitive model, regardless of the confidence of the experimenter in his ability to anticipate the nature of the resulting data.

In sum then, all three hypothesis were confirmed. Vroom's model appears to be a useful tool in divergent performance settings, industrial and otherwise. Furthermore, the data suggest that the model does in fact predict self-rated or perceived performance rather than other performance criteria. And last, perceived ctancy, it appears, must be measured in each test of the model in order to

ustice to the theory.
